4 **Abstract**

5 Dolomite is one of the major mineral forms in which carbon is subducted into the Earth's
6 mantle. End-member $\text{CaMg}(\text{CO}_3)_2$ dolomite typically breaks down upon compression into two
7 carbonates at 5-6 GPa in the temperature range of 800-1200 K (Shirasaka et al. 2002). However,
8 high-pressure X-ray diffraction experiments have shown that dense high-pressure polymorphs of
9 dolomite may be favored over single-cation carbonates (Santillan et al. 2003; Mao et al. 2011;
10 Merlini et al. 2012). Here we compare calculated dolomite structures to experimentally observed
11 phases. Using density functional theory interfaced with a genetic algorithm that predicts crystal
12 structures (USPEX), a monoclinic phase with space group $C2/c$ was found to have lower energy
13 at pressures above 15 GPa than all previously reported dolomite structures. It is possible that this
14 phase is not observed experimentally due to a large activation energy of transition from dolomite
15 I, resulting in the observed second-order phase transition to a metastable dolomite II. Due to the
16 complex energy landscape for candidate high-pressure dolomite structures, a number of
17 structurally unique metastable polymorphs exist. We calculate the equation of state of a set of
18 lowest-energy dolomite polymorphs with space groups $P-1$, $P2/c$ and $C2/c$ up to 80 GPa. Our
19 results demonstrate a need for calculations and experiments on Fe-Mn bearing high-pressure
20 carbonate phases to extend our understanding of Earth's deep carbon cycle and test whether
21 high-pressure polymorphs of double-cation carbonates represent the main reservoir for carbon
22 storage within downwelling regions of Earth's mantle.

23 Keywords: dolomite, ab initio, global carbon cycle, lower mantle, high pressure

24 **Introduction**

25 Carbon is exchanged between the surface and Earth's interior through ingassing by
26 subduction and through both passive and volcanic outgassing (Kelemen and Manning 2015).
27 Carbon is subducted into the mantle primarily in the form of carbonate (CO_3^{2-} -bearing) minerals
28 as metasomatically calcium-enriched basaltic rock (rodingite), calcified serpentinites
29 (ophicarbonates) and sedimentary carbonaceous ooze (Brenker et al. 2006). Evidence of carbon-
30 bearing phases in the Earth's mantle includes: the release of CO_2 in volcanic eruptions, dissolved
31 CO_2 in magmatic glasses and glass inclusions (Mörner and Etiope 2002), diamonds and
32 carbonate minerals in mantle xenoliths (Eggler 1978; Sobolev and Shatsky, 1990), and the
33 existence of carbonatite and kimberlite magmas (Wyllie et al. 1990). Carbon has low solubility
34 in mantle silicates (Shcheka et al. 2006), such that significant carbon storage or transport in the
35 mantle requires formation of carbon-rich phases. Decomposition of carbonates can produce free
36 CO_2 , which lowers the viscosity and melting temperature of the surrounding mantle (Eggler et al.
37 1976) and enables rapid recycling of carbon through subduction-related volcanism rather than
38 deep subduction and long-term storage. Identifying and characterizing the stability of carbonate
39 phases is therefore a necessary step towards understanding the transport and storage of carbon
40 through the Earth's deep carbon cycle (Hazen et al., 2013). The identification of a new, more
41 stable carbonate phase that is able to host carbon under conditions where known carbonates may
42 decompose has the potential to substantially change estimates of the geochemical fluxes of
43 carbon.

44 It has been suggested that magnesite is the dominant carbonate phase in relatively
45 oxidized regions of the mantle (Brenker et al. 2006; Isshiki et al. 2004). Skorodumova et al.
46 (2005), reasoning by analogy to silicates, examined the stability of magnesite in selected
47 pyroxene and perovskite structures, finding that magnesite could transform into a $C2/c$ pyroxene
48 structure with 4-fold coordination of carbon by oxygen at 113 GPa. Using USPEX, however,
49 Oganov et al. (2008) searched a vastly larger space of possible structures and found that
50 magnesite undergoes a phase transition at 84 GPa to a monoclinic phase (“phase II”) with space
51 group $C2/m$, containing rings of $(C_3O_9)^{6-}$, and subsequently at 138 GPa transitions to an
52 orthorhombic phase (“phase III”) with space group $P2_1$, containing chains of CO_4^{4-} tetrahedra.
53 Their calculations show that the $C2/c$ pyroxene structure has a higher energy than either phase II
54 or phase III at all relevant pressures. Calcite, on the other hand, transitions to aragonite at 2 GPa,
55 which transitions to the post-aragonite phase (space group $Pm\bar{m}n$) at 42 GPa, persisting up to
56 core-mantle boundary pressures (Ono et al. 2005; Oganov et al. 2006).

57 End-member $CaMg(CO_3)_2$ dolomite typically breaks down into two carbonates at about
58 5-6 GPa in the temperature range of 800-1200 K (Shirasaka et al. 2002). However, X-ray
59 diffraction experiments have proposed that dense high-pressure phases of dolomite may be more
60 stable or comparable in stability to single-cation carbonates above 35 GPa. High-pressure
61 dolomite may be resistant to decomposition into single-cation carbonates prior to the
62 transformation of trigonal magnesite to monoclinic phase II. Santillan et al. (2003) observed a
63 phase transition of $CaMg(CO_3)_2$ dolomite to a new phase (“dolomite II”) at about 20 GPa.
64 Experiments on two Fe-bearing compositions, $Ca_{0.988}Mg_{0.918}Fe_{0.078}Mn_{0.016}(CO_3)_2$ (Mao et al.
65 2011) and $CaMg_{0.6}Fe_{0.4}(CO_3)_2$ (Merlini et al. 2012), led to observations of two phase transitions
66 in dolomite at 17 and 35 GPa. Both studies refer to the high-pressure phases as “dolomite II” and

67 “dolomite III,” and find that dolomite II decomposes upon heating while dolomite III is resistant
68 to decomposition into single-cation carbonates at high pressure and temperature. However, they
69 report different high-pressure dolomite phases. Mao et al. (2011) characterize their observed
70 dolomite II with orthorhombic symmetry and dolomite III with monoclinic symmetry, but did
71 not refine atomic coordinates or identify the space groups. Merlini et al. (2012) characterize their
72 high-pressure dolomite phases with triclinic symmetry, refining both the crystal structures and
73 atomic coordinates. The X-ray diffraction patterns for the dolomite II structures are consistent
74 with each other (see supplementary materials for Merlini et al. (2012)), whereas the dolomite III
75 structures have distinct X-ray diffraction patterns resulting from nonequivalent crystal structures.
76 The difference in symmetry reflects the complex nature of dolomite polymorphs, whose stability
77 and transformation kinetics may be strongly affected by variations in composition and
78 experimental conditions. As already seen in comprehensive structure searches for MgCO_3 , it is
79 likely that Fe-Mn-bearing $\text{CaMg}(\text{CO}_3)_2$ has a complex energy landscape, resulting in many
80 polymorphs with similar energies. Even after sample annealing, it may be that the most stable
81 phase is never achieved experimentally or that slight variations in composition result in different
82 ground states.

83 In addition to a difference in symmetry, the two studies report different unit-cell volumes
84 for dolomite II and dolomite III, with discrepancies larger than can be explained simply by the
85 difference in composition. Mao et al. (2011) report a 15% unit-cell volume drop upon the phase
86 transition from dolomite I to dolomite II, whereas Merlini et al. (2012) do not observe a
87 detectable change in volume. For the phase transition from dolomite II to dolomite III, Mao et al.
88 (2011) report an 8% volume drop and Merlini et al. (2012) report a 3% volume drop. Although it
89 is possible that the difference in unit cell volumes for the high pressure phases is a result of the

90 combined effect of different compositions, crystal structures and experimental conditions,
91 Merlini et al. (2012) propose that a different choice of formula units per unit cell is required to
92 correctly index the structure of Mao et al. (2011). In any case, the differing experimental
93 observations create a need for a theoretical study to confirm which high-pressure dolomite
94 phases are the most thermodynamically stable.

95 **Computational Methods**

96 USPEX (Universal Structure Predictor: Evolutionary Xtallography), an evolutionary
97 algorithm that can be interfaced with a variety of density functional theory codes, has been
98 shown to successfully predict stable phases without experimental input (Oganov and Glass,
99 2006). USPEX compares the energies of structures that continuously evolve through operations
100 of (1) heredity – a combination of two parent structures, (2) lattice mutations – a distortion of the
101 cell shape through a symmetric strain matrix, and (3) atomic permutations – switching of atoms
102 within the cell. We ran USPEX interfaced with the ab initio code VASP (Kresse and Furthmuller
103 1996) for $\text{CaMg}(\text{CO}_3)_2$ with 20 or 30 atoms/cell at 25-40 GPa pressure, with population sizes
104 between 30 and 50 structures per generation. Ab initio calculations were performed at 0 K using
105 the projector-augmented wave (PAW) method (Blochl, 1994) implemented in VASP. The
106 generalized gradient approximation (GGA) (Perdew et al. 1996) was used to approximate the
107 exchange correlation terms. In structure prediction calculations, GGA produces results better
108 than LDA in terms of agreement with experiments for phase transition pressures and chemical
109 reactions (Oganov et al. 2013). The following PAW pseudo-potentials were used in VASP for
110 structure prediction: core radius of 3.7 a.u. for Ca ($1s^2 2s^2 2p^6$ core, $3s^2 3p^6 4s^2$ valence), 2.0 a.u. for
111 Mg ($1s^2 2s^2 2p^6$ core, $3s^2$ valence), 1.5 a.u. for C ($1s^2$ core, $2s^2 2p^2$ valence), and 1.52 a.u. for O
112 ($1s^2$ core, $2s^2 2p^4$ valence).

113 These calculations were run several times both with and without prescribed seed
114 structures. The first generation was created either entirely randomly or with 1-3 seeded structures
115 with standard physical constraints on the minimum ion distance of 0.7 Å and minimum lattice
116 vector of 2-2.5 Å. For subsequent generations, 40-50% of the structures were created through
117 heredity using the lowest energy structures from the previous generation, 10-20% were produced
118 through lattice mutations, 10% were produced through atomic permutations and 20% were
119 randomly generated. The best five structures in each generation were left unchanged and
120 competed in subsequent generations. Generated structures were relaxed at constant pressure in
121 four stages with incrementally increasing precision, where the final plane-wave energy cut off, k-
122 point resolution and convergence criteria for electronic self-consistency were 550 eV, 0.08 Å⁻¹
123 and 10⁻⁵ eV, respectively. Through this procedure, we were able to find a 20-atom monoclinic
124 dolomite with *P2/c* symmetry and a 20-atom primitive *C2/c* cell to which we applied a
125 crystallographic transformation matrix to obtain the conventional 40-atom monoclinic *C2/c*
126 structure. Due to the complex nature of the free energy landscape for double carbonates, it is
127 possible that a global minimum was never achieved.

128 A *C2/c* structure with 4-fold C was created by substituting the dolomitic composition into
129 the diopside structure and relaxing it at high pressure. We also examined the triclinic dolomite II
130 and dolomite III structures from Merlini et al. (2012), and we substituted the dolomitic
131 composition into several previously published carbonate structures: the post-aragonite structure
132 (*Pmnm*) (Oganov et al. 2006); MgCO₃ phase II (*C2/m*), phase III (*P2₁*), structure *P2₁-10* and
133 structure *Pna2₁-20* (Oganov et al. 2008); calcite III (*C2*) (Smyth and Ahrens 1997); and MnCO₃
134 phase II (*P-1*) (Merlini et al. 2015). Appropriate supercells with the dolomite stoichiometry were
135 created with various choices of cation site ordering (i.e., layers of Ca/Mg atoms and checkered

136 Ca/Mg arrangement). The $P2_1-10$ structure has the space group $C2$ after relaxing it at high
137 pressures with the dolomite stoichiometry. The resulting structure was crystallographically
138 transformed to a conventional $C2$ unit cell, and resembles the $P2/c$ structure. The relaxed calcite
139 III structure extended to a $1 \times 1 \times 2$ supercell with layers of Ca and Mg atoms is equivalent to the
140 $C2$ structure with a different unit cell. These structures from the literature and several
141 competitive structures found with USPEX are not considered further in this study due to their
142 relatively high energies. However, it is possible that, with certain cation substitutions, these
143 phases may be observed experimentally. Hence, all of these structures are provided in the
144 supplementary crystallographic information file.

145 Finally, the short list of low-energy candidate dolomite structures remaining after USPEX
146 and literature search were relaxed using more accurate PAW pseudo-potentials for the 3rd-row
147 elements: core radius of 2.3 a.u. for Ca ($1s^2 2s^2 2p^6$ core, $3s^2 3p^6 4s^2$ valence) and 2.0 a.u. for Mg
148 ($1s^2 2s^2$ core, $2p^6 3s^2$ valence). C and O pseudo-potentials remained the same. A plane-wave
149 energy cut off of 600 eV was used and a fine k-point grid of $0.02-0.03 \text{ \AA}^{-1}$ was required to refine
150 the transition pressures between phases with similar energies. We carried out all the requisite
151 convergence tests to ensure these parameters were adequate. The convergence criteria for
152 electronic self-consistency and ionic relaxation loop are 10^{-5} eV and 10^{-4} eV, respectively. We
153 ensured that forces acting on all relaxed atoms were $<0.01 \text{ eV/\AA}$.

154 The pressure-volume data were fitted with third-order Birch-Murnaghan equations of
155 state using MINUTI 1.1.2 (Sturhahn 2015). For dolomite III and $P2/c$ dolomite, equations of
156 states were fitted above 10 GPa; at lower pressures, these structures transform into lower-
157 pressure polymorphs with coplanar CO_3^{2-} groups during structural relaxation. Similarly, in $C2/c$
158 dolomite with 4-fold C, the carbonate tetrahedra transform to triangular coordination

159 environments below 60 GPa. Thus, for the *C2/c* structure with 4-fold C, equation of state
160 parameters V_0 , K_0 and K_0' , though defined at 0 pressure, are fitted to data in the range from 60 to
161 140 GPa. Conversely, the dolomite II structure is not stable above 30 GPa; thus, an equation of
162 state was fitted to the pressure range between 0 and 30 GPa. Structures *C2/c* with 3-fold C and
163 dolomite I were fitted with equations of state at pressures between 0 and 80 GPa.

164

Results

165 We found two competitive $\text{CaMg}(\text{CO}_3)_2$ structures with *C2/c* and *P2/c* symmetry using
166 USPEX (Fig. 1). Simulated X-ray diffraction patterns are shown in Figure 2. The enthalpy
167 difference between candidate high-pressure dolomite polymorphs and *R-3* dolomite I are shown
168 in Figure 3. For static ab initio calculations, the enthalpy is equivalent to Gibbs free energy; the
169 structure with the lowest enthalpy is the most stable structure. Dolomite II is energetically
170 similar to dolomite I and was not successfully relaxed above 30 GPa without the rotation of its
171 CO_3 groups (i.e., a second order phase transition). The *P2/c* structure is less stable than the *C2/c*
172 structure at all pressures examined in this study but more stable than the dolomite III structure
173 above 32 GPa. Above 15 GPa, the *C2/c* structure is more favorable than all other structures
174 discovered by USPEX in this study and all previously reported structures. There is a shift from
175 sp^2 bonding (triangular coordination) to sp^3 bonding (tetrahedral coordination) in the *C2/c*
176 structure at 127.5 GPa (Fig. 3 inset).

177 The pressure-volume relationship for the candidate dolomite phases and their
178 corresponding third-order Birch-Murnaghan equations of state (EOS) are shown in Figure 4. The
179 zero-pressure volume per CO_3^{2-} group (V_0), bulk modulus (K_0) and the bulk modulus derivative
180 (K_0') for these structures are compared in Table 2. The fitted K_0 and K_0' for dolomite I are

181 86.8(3) GPa and 4.20(2) with a V_0 of 55.1 Å³, in reasonable agreement with reported equation of
182 state parameters determined from fitting a Birch-Murnaghan EOS to pressure-volume data from
183 X-ray diffraction experiments: $V_0=53.4(1)$ Å³, $K_0=94.1(7)$ with a fixed K_0' of 4 (Ross and
184 Reeder 1992). The volume of dolomite I is overestimated by 3.3%, which is typical for the GGA
185 method. We fitted the experimental pressure-volume data for Ca(Mg_{0.6}Fe_{0.4})(CO₃)₂ dolomite III
186 (Merlini et al. 2012) with a third-order Birch Murnaghan EOS using a prior estimate of 4 and
187 prior window of ±1 for K_0' , resulting in $V_0=51.8(1.6)$ Å³, $K_0=92.7(20.0)$ GPa and $K_0'=3.92(4)$.
188 These results are in good agreement with the equation of state parameters fitted to the calculated
189 dolomite III compression data where $V_0=52.2(1)$ Å³, $K_0=94.1(9)$ GPa and $K_0'=3.89(3)$.

190 For high-spin Ca(Mg_{0.92}Fe_{0.08})(CO₃)₂ dolomite III, Mao et al. (2008) report a $K_0=164(4)$
191 with a $K_0'=4$ (fixed), resembling the compression behavior of our calculated *C2/c* dolomite with
192 4-fold coordination. The zero-pressure bulk moduli for all phases with triangular (CO₃)²⁻ groups
193 range from 80 to 90 GPa, whereas the K_0 for the *C2/c* structure with 4-fold C is 180 GPa, more
194 than twice as large as for the *C2/c* structure with 3-fold C. By 80 GPa, however, the difference in
195 bulk moduli decreases to 30 GPa (Fig. 4 inset). Nevertheless, a high bulk modulus for high-
196 pressure carbonates may be an indication of 4-fold coordinated C.

197

Discussion

198 In mantle silicates, Si changes from 4-fold to 6-fold coordination at the decomposition of
199 ringwoodite to bridgmanite and periclase. In MgCO₃, C forms tetrahedra above 82 GPa, whereas
200 in CaCO₃, C remains 3-fold coordinated up to core-mantle boundary pressures, only forming
201 tetrahedra above 137 GPa (Oganov et al. 2008; Boulard et al., 2015). In *C2/c* dolomite, C
202 tetrahedra become stable at 127.5 GPa, an intermediate pressure compared to the tetrahedra-

203 forming pressures for the single-carbonate end members, MgCO_3 and CaCO_3 . Prior to these
204 calculations, there have been no reports in the literature addressing whether C in double
205 carbonates, such as dolomite, would become tetrahedrally coordinated at lower mantle pressures.

206 With increasing pressure, Mg, Fe^{2+} and Ca in mantle silicates transition from 6-fold
207 coordination in olivine and pyroxenes to 6- and 8-fold coordination in garnets and then to 6- and
208 12-fold coordination in bridgmanite (Murakami et al. 2004; Oganov and Ono 2004). In CaCO_3 ,
209 Ca increases in coordination number from 6 in calcite to 9 in aragonite to 12 in post-aragonite
210 while, in MgCO_3 , Mg atoms increase in coordination from 6 in magnesite to 8-10 in phases II
211 and III to 9 in $Pna2_1-20$ (Oganov et al. 2008). In the dolomite III structure (Merlini et al. 2012),
212 the coordination numbers are variable, ranging from 7 to 10, with Ca occupying the larger sites.
213 In $C2/c$ dolomite, Mg is 6-fold coordinated and Ca is 8-fold coordinated up to at least 140 GPa.
214 Although, at high pressure, $C2/c$ dolomite is the least dense $\text{CaMg}(\text{CO}_3)_2$ candidate, it is stiffer
215 than all the other considered phases in this study, a result of the persistence of relatively low
216 coordination values for its metal cations.

217 Our simulations show that dolomite has many energetically competitive polymorphs at
218 high pressure with similar enthalpies to the $P2/c$ and dolomite III structures; however, above 15
219 GPa, the $C2/c$ structure with 3-fold C has a lower energy than all other phases found with
220 USPEX and reported structures in literature. It is possible that the $C2/c$ structure has not been
221 observed experimentally due to a high activation barrier and/or a high sensitivity of the crystal
222 symmetry to iron concentration. Additionally, it is very likely that the stability of high-pressure
223 dolomite with respect to decomposition into single-cation carbonates is related to its
224 composition.

225 Pure high-pressure dolomite phases will likely decompose into single-cation carbonates
226 at high pressures. The rapid decrease of the enthalpy of high-density post-aragonite beyond 42
227 GPa is the main driver of the predicted breakdown of all dolomites into single-cation carbonates,
228 including the most stable *C2/c* polymorph (Fig. 5). However, the addition of Fe and Mn is likely
229 to stabilize dolomite with respect to decomposition. A careful treatment of iron is necessary to
230 accurately describe the strongly correlated nature of the *d*-electrons using self-consistently
231 calculated Hubbard *U* parameters, which are a function of iron concentration, spin state, crystal
232 symmetry and unit-cell volume. Additionally, the effect of temperature on high-pressure
233 dolomite phases is unknown. The stability field of pure dolomite I increases with increasing
234 temperature, decomposing at about 4 GPa at 400 K and 6 GPa at 1200 K (Martinez et al. 1996).
235 It is possible that a similar trend is true for high-pressure dolomite polymorphs. Additional
236 calculations and experiments on Fe-bearing dolomites at high temperatures and pressures are
237 needed.

238 **Implications**

239 The behavior of high-pressure carbonates influences the global carbon cycle and,
240 subsequently, global climate over geologic time scales. The feedbacks inherent in the formation
241 and destruction of carbonate and the role of carbonate in storage of the potent greenhouse gas
242 CO₂ are central to maintaining the habitability of our planet. It has been suggested that Ca-Mg-
243 Fe carbonates play a leading role in transporting and storing carbon in the deep earth (Brenker et
244 al. 2007; Boulard et al. 2012). Although the present study of pure CaMg(CO₃)₂ dolomite has
245 identified new, more stable high pressure phases than those previously known, it has not yet
246 changed our understanding of the ultimate stability of double carbonates relative to their
247 decomposition products. However, when Fe is considered in future calculations, we may find

248 that high-pressure polymorphs of Fe-bearing dolomite could in fact represent the main reservoir
249 for carbon storage within sections of the Earth's mantle. Combined with thermodynamic,
250 geochemical and tectonic models, these results will help us understand the effect of the global
251 carbon cycle on long-term climate change.

252 **Acknowledgments**

253 We would like to thank Edwin Schauble, Abby Kavner, Marco Merlini, Greg Finkelstein, Artem
254 Oganov and Olle Hellman for valuable discussions and insights. We are thankful to Naveed
255 Near-Ansari for assistance with technical aspects using FRAM, the high-performance computing
256 cluster at Caltech. This work is supported by the US National Science Foundation through award
257 EAR-1551433.

Figure Captions

339 Figure 1. Novel high-pressure dolomite polymorphs at 80 GPa: (a) *C2/c* dolomite with 3-fold C,
340 (b) *C2/c* dolomite with 4-fold C and (c) *P2/c* dolomite. Figures were produced with the VESTA
341 software (Momma and Izumi 2008). Ca polyhedra are blue, Mg polyhedra are grey and C
342 polyhedra are orange.

343 Figure 2. Synthetic X-ray diffraction patterns for high-pressure dolomite phases at 80 GPa
344 ($\lambda=1.54 \text{ \AA}$). Dolomite III is blue, *C2/c* dolomite with 3-fold C is red, *C2/c* dolomite with 4-fold C
345 is grey and *P2/c* dolomite is orange.

346 Figure 3. Enthalpies per formula unit of candidate dolomite structures relative to dolomite I
347 (horizontal line at zero). *C2/c* dolomite is energetically more stable than all other phases
348 examined in this study for the $\text{CaMg}(\text{CO}_3)_2$ composition. Inset shows the enthalpy (H) per
349 formula unit of *C2/c* dolomite 4-fold C relative to *C2/c* dolomite with 3-fold C. The transition
350 from sp^2 bonding (triangular coordination) to sp^3 bonding (tetrahedral coordination) of C in the
351 *C2/c* structure occurs at 127.5 GPa.

352 Figure 4. Pressure-volume data and the fitted third-order Birch Murnaghan equations of state for
353 candidate dolomite phases. Experimental pressure-volume data for $\text{CaMg}_{0.6}\text{Fe}_{0.4}(\text{CO}_3)_2$ are
354 shown in grey “+” symbols, with a second-order phase transition to dolomite II at 17 GPa and a
355 first-order phase transition to dolomite III at 35 GPa (Merlini et al. 2012). The equation of state
356 for *C2/c* dolomite with 4-fold C was calculated from data at 60-140 GPa in intervals of 5 GPa.
357 Inset shows the fitted bulk modulus as a function of pressure. Structures *C2/c* and *P2/c* have
358 indistinguishable bulk moduli.

359 Figure 5. The enthalpy difference between dolomite polymorphs and aragonite + magnesite. The
360 rapid decrease of the enthalpy of the post-aragonite + magnesite assemblage is the main driver of
361 the breakdown of all dolomites into single-cation carbonates. However, the substitution of Fe for
362 Mg is likely to stabilize *C2/c* dolomite with respect to decomposition.

366

367 Table 2. Equation of state parameters for the calculated $\text{CaMg}(\text{CO}_3)_2$ and experimental
368 $\text{Ca}(\text{Mg,Fe})(\text{CO}_3)_2$ polymorphs. We fitted the pressure-volume data using a third-order Birch-
369 Murnaghan equation of state with the MINUTI software, applying a 1% error to pressure and
370 volume. V_0 is the zero-pressure volume per CO_3^{2-} group. Dolomite III and structures $P2/c$ and
371 $C2/c$ with 4-fold C were not successfully relaxed at 0 GPa without a second-order phase
372 transition to a lower-pressure structure. Thus, their zero-pressure volumes were fitted.

Phase	V_0 (\AA^3)	K_0 (GPa)	K_0'
dolomite I	55.1	86.8(3)	4.20(2)
dolomite II ^a	55.0	94.0(8)	2.80(7)
dolomite III ^b	52.2(1)	94.1(9)	3.89(3)
dolomite III ^c (Mao et al. 2011)	39.9(3)	164(8)	4
dolomite III ^d (Merlini et al. 2012)	51.8(1.6)	92.7(20.0)	3.92(4)
$C2/c$ (3-fold C)	51.9	84.8(6)	4.78(5)
$C2/c$ (4-fold C)	45.1(3)	178.4(8.1)	3.69(9)
$P2/c$	51.2(1)	85.4(1.4)	4.76(6)

373
374 ^a We fitted an equation of state to our calculated pressure-volume data for the triclinic dolomite II
375 structure reported in Merlini et al. (2012).

376 ^b We fitted an equation of state to our calculated pressure-volume data for the triclinic dolomite III
377 structure reported in Merlini et al. (2012).

378 ^c Equation of state parameters as reported in Mao et al. (2011) for their observed monoclinic dolomite III
379 structure. K_0' was fixed to 4. The full composition as determined from microprobe analysis is
380 $\text{Ca}_{0.988}\text{Mg}_{0.918}\text{Fe}_{0.078}\text{Mn}_{0.016}(\text{CO}_3)_2$. It is possible that the volume of dolomite III is underestimated due to
381 an incorrect assumption of the number of formula units per unit cell (Merlini et al. 2012).

382 ^d We fitted an equation of state to the published experimental pressure-volume data for triclinic dolomite
383 III, with the chemical formula $\text{CaMg}_{0.6}\text{Fe}_{0.4}(\text{CO}_3)_2$ (Merlini et al. 2012). We used a prior estimate of 4
384 and prior window of ± 1 for K_0' .
